# FEP – the forecast evaluation package for *gretl*

Artur Tarassow and Sven Schreiber\*

### based on FEP version 2.1, February 2018

### **Abstract**

The FEP function package for the *gretl* program is a collection of functions for computing different types of forecast evaluation statistics as well as tests. For ease of use a common scripting interface framework is provided, which is flexible enough to accommodate future additions. Most of the functionality is also accessible through a graphical dialog window interface within gretl. This documentation explains the usage and capabilities as well as providing some econometric background where necessary.

### 1 Introduction

The FEP function package is a collection of gretl functions for computing different types of forecast evaluation statistics as well as tests. *Gretl* is an open-source econometrics and statistics program that offers both a command line and a graphical menu-driven interface. Its core functions are implemented in C, but it also comprises a versatile scripting and matrix language named *hansl* which can be used to develop contributed function packages easily. FEP is such a package written in hansl. More information on gretl can be found online at http://gretl.sf.net. The FEP package currently comprises the functions listed in table 1. In section 6 we explain the easy usage from gretl's menu-driven interface (GUI), but until then we focus on the scripting way of performing the analysis. A function package can be downloaded and installed simply by invoking the install command:

install FEP

Then, in each work session, as with all function packages the FEP package needs to be loaded by:

include FEP.gfn

# 2 The applyFCtests() function

This is a convenient top-level function which calls the other test functions in the background as needed. The standard workflow is to define the needed gretl bundle<sup>1</sup> with your input data and choices, and then call this function with the appropriate string code. Here's an example with the Mincer&Zarnowitz test:

<sup>&</sup>lt;sup>1</sup>A "bundle" is a flexible gretl datatype which is basically a collection of other gretl objects. See section 10.7 of the gretl user guide (as of November 2017).

			Included functions
#	Function	Code	Description
1	applyFCtests()		Top-level function
2	doDMtest()	DM	Diebold & Mariano regression based test on forecast
			accuracy
3	doMZtest()	MZ	Mincer & Zarnowitz regression based test on optimal
			(point) forecasts
4	doHPtest()	HP	Holden & Peel extension of the Mincer & Zarnowitz
			regression based test
5	doCGtest()	CG	Campbell & Ghysels sign or signed rank (Wilcoxon type)
			tests for unbiasedness or efficiency of forecasts
6	doEKTtest_series()	EKT	Elliott, Komunjer & Timmermann test of forecast
			rationality under flexible loss
7	doDLtest()	DL	Diebold & Lopez direction of change test
8	doKS()	KS	Computes the (Hanssen-) Kuipers Score for forecasts of
			binary outcomes
9	doPTtest()	PT	Pesaran & Timmermann test on market timing
10	DrawLoss()		draws a single loss function and its associated confidence
			interval
11	DrawLoss2()		draws two loss functions and their associated confidence
			intervals
12	getLoss()		calculate the (forecast error) loss series
13	doPS() / probscore()	PS	calculate the log and quadratic probability scores for
	· · · · · · · · · · · · · · · · · · ·		forecasts of binary outcomes

T-1-1- 1. I. -1. . 1 - 1 (.... . C - ...

```
bundle b
series b.y = growth # assuming 'growth' exists in current workfile
series b.fc = myforecast # ditto
applyFCtests(&b, 'MZ'')
```

The first three lines set up the bundle and put some relevant data in it.<sup>2</sup> Note that the names "y" and "fc" need to match exactly and are case sensitive. See table 2 for the possible and/or necessary bundle elements and their names, which depends on the test that you wish to perform. Note that it is possible to store additional elements in the bundle that are not used by a certain test. Therefore you can set up the bundle once and then pass it around as an input to various tests.

In the last line some things are noteworthy: The applyFCtests() function does not have any return value, so the function call stands for itself without any assignment to a variable. The results of the tests are instead added to the bundle ("b" here) that is passed to the function. To actually enable the function to change the input bundle we need to pass it in so-called pointer form, which just means to preprend the ampersand character: "&b". Finally, a string code must be specified

<sup>&</sup>lt;sup>2</sup>If you're obsessed with saving lines of code, you might instead use something like the following: bundle b = defbundle("y",growth, "fc",myforecast).

<sup>&</sup>lt;sup>3</sup>See "Function programming details", section 13.4 of the gretl user guide (as of November 2017).

to indicate which test should be run, where the possible codes are given in table 1. There are also some supplementary functions in that table which do not have a string code; those functions have to be called directly and cannot be accessed through applyFCtests(). But several string codes may be included in one call to applyFCtests(), separated by spaces.

If the function is called like this, then there will typically be some printed output showing the test results. The details depend on the respective background function, see the corresponding documentation below. The other possibility to access the results is to inspect the new members that are added to the bundle. Again, see the documentation below to learn which new members each function adds to the bundle.

### 3 Forecast descriptive statistics

### 3.1 Calculate the (forecast error) loss

The function getLoss() helps to calculate the forecast losses (disutilities) implied by the given forecast errors, according to various loss function assumptions such as lin-lin, square, linex, double linex. See table 3.

#### 3.2 Draw some loss functions

Draw a single (DrawLoss) or two (DrawLoss2) loss functions and its associated confidence interval. See table 4.

### 3.3 Tools for binary outcomes

### 3.3.1 The Kuipers Score (KS)

The (Hanssen-) Kuipers Score (KS) is used to evaluate binary outcomes. Let  $f = \{0,1\}$  be a forecast of the binary variable  $y = \{0,1\}$ . The KS is defined as the difference between the probability of detection (POD) and the probability of false detection (POFD).<sup>4</sup> The POD is the proportion of times where y = 1 is correctly predicted. The POFD is the proportion of times where y = 1 is wrongly predicted. Thus, KS is defined as KS = POD - POFD. See table 5 for the function interface and elements.

### 3.3.2 Probability scores – doPS() and probscore()

The probscore() function computes forecast accuracy statistics used for probability forecasts. The observed outcome is still binary, but in contrast to the Kuipers score

<sup>&</sup>lt;sup>4</sup>The terminology is not universal it seems. Sometimes the POD might be called hit rate, whereas usually the hit rate denotes something else. Similarly with the POFD and the false alarm rate.

	Tak	ole 2: Bund	lle membe	ers neede	d for each	function			
	CG	DL	DM	EKT*	HP	MZ	KS	PT	PS

		strii	ıg input (c	ptional)					
Loss drawing				[lossdra	w]				

### Notes:

robust can be 0 (default) or 1 (use HAC/robust SE);

loss can be 1 (U-shape, default) or 2 (V-shape);

verb can be 0 (no details, default) or 1 (print details);

lossdraw can be "no" (default), "display", or consist of path + filename;

*fcup* is binary, not a probability;

*k* can be 0 (default, no test on lags) or a positive (not too large) integer; note that only a single lag is tested;

*a*0 can be between 0 and 1 (non-integer, default 0.5).

\*: EKT refers to the doEKTtest\_series() variant. For the matrix-based variant doEKTtest() see the source code.

Table 3: Forecast error loss				
Function	<pre>getLoss(matrix fce, string LF[null], matrix param[null], matrix realiz[null])</pre>			
Description	Calculate the (forecast error) loss			
Return type	matrix			
Function arguments	matrix <i>fce</i> : T by k matrix of forecast errors; if <i>realiz</i> is given, <i>fce</i> is understood as the forecasts themselves string <i>LF</i> (optional): specify loss function: "ll" (linlin), "qq" (or "quadquad"), "sq" (or "square", default), "abs", "linex" (Varian), "dlinex" (or "dle") for double linex (Granger) matrix <i>param</i> (optional): loss function parameter(s), default 0.5; <i>param</i> must be a 1-element or 2-element vector matrix <i>realiz</i> (optional): matrix of realizations			
Output	Returns a matrix with forecast error losses, of the same (T x k) dimension as the input matrix.			
Reference	Varian [1975], Granger [1999]			

Notes: About input format for *param*: For gretl versions until 2017a scalar values must explicitly be provided as a pseudo matrix (e.g {0.4}) while for later versions, gretl accepts a scalar as a 1x1 matrix.

the forecast here is a continuous probability. See table 6. The doPS() function is just a thin wrapper around probscore that is harmonized with the evaluation test functions in the package; see table 7.

### 4 Evaluation of individual forecasts

### 4.1 Mincer-Zarnowitz test on forecast unbiasedness – doMZtest()

Define the h-step ahead forecast made in t as  $f_{t+h+t}$  and the actual outcome as  $y_{t+h}$ . Mincer&Zarnowitz suggest to run the regression:

$$y_{t+h} = \beta_0 + \beta_1 f_{t+h|t} + u_{t+h}$$

Unbiasedness is viewed as a joint test of  $\beta_0 = 0$  and  $\beta_1 = 1$ . Usually the corresponding test statistics is compared with asymptotic critical values from the F-distribution. H0: Forecast is unbiased and efficient. H1: Forecast is biased and/or inefficient. Intercept will be automatically inserted.

However, remaining serial correlation in  $u_{t+h}$  yields inefficient estimates. Also the small sample properties are unknown. To account for these two potential sources of inefficiency, the user can compute HAC robust standard errors as well as bootstrap p-values.

See table 8 for a synopsis.

Table 4: Draw losses					
Function	<pre>DrawLoss(int p, scalar aT, scalar V, string fpath[null])</pre>				
Description	Draw (forecast error) loss				
Return type	none (void)				
Function arguments	int $p$ : loss function type parameter, $1 = \text{lin-lin}$ , $2 = \text{quad-quad}$ scalar $aT$ : loss function shape parameter $\alpha \in [0, 1]$ scalar $V$ : estimated variance of $aT$ string $fpath$ (optional): null = display figure (default) or provide complete "path+file name" to store figure				
Output	displays plot (or saves to file path)				
Function  Description Return type	DrawLoss2(int p, scalar aT1, scalar V1, scalar aT2, scalar V2, string fpath[null]) Draw two (forecast error) losses none (void)				
Function argum	int $p$ : loss function type parameter, $1 = \text{lin-lin}$ , $2 = \text{quad-quad}$ scalar $aT1$ : loss function shape parameter $\alpha \in [0, 1]$ scalar $V1$ : estimated variance of $aT1$ scalar $aT2$ : loss function shape parameter $\alpha \in [0, 1]$ scalar $V2$ : estimated variance of $aT2$ string $fpath$ (optional): null = display figure (default) or provide complete "path+file name" to store figure				
Output	displays plot (or saves to file path)				

	lable 5: Kuipers Score			
Function Description Return type	doKS(bundle *b) compute the Kuipers Score none (void)			
Function arguments	Pointer to the model bundle. This bundle includes as members: series <i>yup</i> : binary-valued series of actuals that takes the value of unity for ups and otherwise zero series <i>fcup</i> : binary-valued forecast that takes the value of unity for ups otherwise zero scalar <i>verb</i> : 0 = no printout, 1 = print details			
Output	The following new elements are stored into the model bundle: scalar <i>KSstat</i> : Kuipers score matrix <i>KSmat</i> : matrix holding all classifications			
Reference	Pesaran [2015, p. 396]			
	Table 6: Probability scores			
Function Description Return type	probscore(matrix y, matrix Pr) computes the log (LPS) and quadratic (QPS) probability scores matrix			
Function arguments	matrix <i>y</i> : binary-valued vector of actuals that takes the value of unity for ups and otherwise zero matrix <i>Pr</i> : vector of forecast probabilities of			
Output	2-element (1 by 2) vector with QPS, LPS			
Function Description	Table 7: Probability scores wrapper  doPS(bundle *b) computes the log (LPS) and quadratic (QPS) probability scores			
Return type	none (void)			
Function arguments	Pointer to the model bundle. This bundle includes as members: series <i>yup</i> : binary-valued series of actuals that takes the value of unity for ups and otherwise zero series <i>pfc</i> : probability forecast (between 0 and 1) that <i>yup</i> takes the value of unity			
Output	The following new elements are stored into the model bundle: scalar <i>qps</i> : quadratic probability score scalar <i>lps</i> : log probability score

Output	The following new elements are stored into the model			
_	bundle:			
	scalar MZstat: test statistics			
	scalar MZpval: p-value			
Reference	Mincer and Zarnowitz [1969]			

### 4.2 Holden-Peel test on forecast efficiency – doHPtest()

The Mincer-Zarnowitz regression can be extended to include another regressor (or a whole vector of additional regressors),  $Z_t$ , such that (assuming for simplicity that  $Z_t$  is a scalar value)

$$y_{t+h} = \beta_0 + \beta_1 f_{t+h|t} + \beta_2 Z_t + u_{t+h}$$

The hypothesis to test for a strong form of unbiasedness involves the null  $\beta_0 = 0$ ,  $\beta_1 = 1$  and  $\beta_2 = 0$ . An intercept will be automatically inserted.

Again the user can compute HAC robust standard errors and/or bootstrap p-values; see table 9.

### 4.3 Campbell & Ghysels efficiency tests – doCGtest()

Here we understand "efficiency" in a broad sense, comprising unbiasedness for example.

Let us define the one-period forecast errors as  $e_{1t} = y_{t+1} - f_{t+1|t}$ . An indicator function indicates whether the forecast error is positive or negative such that u(z) = 1 if  $z \ge 0$  and u(z) = 0 otherwise. The test statistics of the sign test of unbiasedness of forecast errors is

$$S = \sum_{t=1}^{T} u(e_{1t}),$$

Table 9: Holden-Peel test			
Function	<pre>doHPtest(bundle *b)</pre>		
Description	computes the Holden-Peel variant of the		
	Mincer-Zarnowitz test regression on unbiasedness		
Return type	none (void)		
Function arguments	Pointer to the model bundle. This bundle includes as members:		
	series <i>y</i> : actual observations		
	series <i>fc</i> : h-step ahead forecast		
	list z: gretl list of additional control variables		
	scalar <i>robust</i> : 0 = no robust SEs (default), 1 = compute HAC SEs		
	scalar <i>nboot</i> : 0 = no bootstrap (default), or number of bootstrap iterations		
	scalar $verb$ : 0 = no printout (default), 1 = print details		
Output	The following new elements are stored into the model bundle:		
	scalar HPstat: test statistics		
	scalar <i>HPpval</i> : p-value		
Reference	Holden and Peel [1990]		

where *T* is the number of available forecast errors. While the signed rank test (see below) is defined as

$$W = \sum_{t=1}^{T} u(e_{1t}) R_{1t}^{+}$$

with  $R_{1t}^+$  referring to the rank of each forecast error when  $|e_{1t}|,...,|e_{1T}|$  are placed in ascending order. The forecast errors are independent with zero median. The sign statistic S is binomially distributed with Bi(T, 0.5). Under the additional assumption of symmetrically distributed forecast errors around zero, the test statistics W follows a Wilcoxon signed rank distribution. Note that this test is performed once you set k=0 (or leave it out, as this is the default; see table 10).

This test idea can also be employed to test for serial correlation in the forecast errors. Construct the product series  $Z_{1t}^k = e_{1t}e_{1(t-k)}$  with  $k \ge 1$ , and compute the statistics:

$$S_k = \sum_{t=k+1}^{T} u(Z_{1t}^k)$$
 and  $W_k = \sum_{t=k+1}^{T} u(Z_{1t}^k) R_{2t}^+$ 

where  $R_{2t}^+$  is the signed rank of the product  $Z_{1t}^k$ , t = 1, ..., T. These location tests were proposed by Dufour [1981]. Serial correlation in the forecast errors will move the centre of their product away from zero. The sign statistic  $S_k$  is binomially distributed with Bi(T - k, 0.5). The test statistics  $W_k$  follows a Wilcoxon signed rank distribution of size T - k. Note, both tests on serial correlation require to set the option k > 0, and the necessary product series  $Z_{1t}^k$  will be constructed automatically.

Table 10: Campbell & Ghysels sign and signed rank

Function Description Return type	doCGtest(bundle *b) Campbell & Ghysels sign and signed rank (Wilcoxon-type) tests for unbiasedness or efficiency of forecasts none (void)			
Function arguments	Pointer to the model bundle. This bundle includes as members: series $y$ : actual observations series $fc$ : forecast (or series $E$ : forecast error) scalar $verb$ : $0 = no$ printout (default), $1 = print$ details series $CGX$ (optional): variable for orthogonality (see also $k$ ) scalar $k$ : set $k > 0$ to test efficiency with respect to information at lag $k$ (own lag of forecast error if $X$ is absent), else $k = 0$ (or omit) to test for unbiasedness			
Output	The following new elements are stored into the model bundle: scalar <i>CGSIGNstat</i> and <i>CGWILCstat</i> : test statistic scalar <i>CGSIGNpval</i> and <i>CGWILCpval</i> : p-value			
Reference	Campbell and Ghysels [1995], Campbell and Ghysels [1997], Dufour [1981]			

Notes: The calculation of CGWILCpval, the p-value of the Wilcoxon-type signed rank tests, depends on the WSRpvalue function in the special package "extra" for gretl ( $\geq$ v0.41). Please install that package manually from the gretl package repository if the automatic loading fails.

Lastly, one can use this framework to assess whether the forecast has made efficient use of the available information represented by the series X in t. For this, one needs to construct the product series  $Z_t^k = e_{ht}X_{t-k}^c$  with k > 0 based on the recursively re-centered series  $X_t^c = X_t - \text{median}(X_1, X_2, \dots, X_t)$ . This way of recentering requires, however, that the series  $X_t$  is stationary and has no trend.

The sign and signed rank statistics are given by

$$S_{ok} = \sum_{t=k+1}^{T} u(Z_t^k)$$
 and  $W_{ok} = \sum_{t=k+1}^{T} u(Z_t^k) R_{1t}^+$ ,

noting that the ranks used refer to the forecast errors, not to  $Z_t^k$ , to obtain a statistic with a known and valid distribution; see Campbell and Ghysels [1995, pp. 3] or Campbell and Ghysels [1997, p. 560] for a discussion.<sup>6</sup> This orthogonality test can be achieved by passing the series as CGX in the bundle. See table 10.

### 4.4 Elliott, Komunjer, and Timmermann test with asymmetric loss – doEK-Ttest()<sup>7</sup>

This is a test for forecast rationality that allows for asymmetric loss. As a side product the parameters of a general class of loss functions can be estimated.

Elliott et al. [2005] propose a flexible class of loss functions, the so-called EKT loss function:

$$L(e) = [\alpha + (1 - \alpha)\mathbf{I}(e < 0)] |e|^p, \quad \alpha \in [0, 1]$$

where **I** is an indicator function which equals one if the forecast error e = y - f < 0, and otherwise zero. Asymmetric loss is given for  $\alpha \neq 0.5$ , and where values exceeding 0.5 indicate greater aversion to positive forecast errors. Setting p = 1 results in a lin-lin loss function with possibly different slopes under asymmetric loss. The quadratic loss function is given for the special setting p = 2 and  $\alpha = 0.5$ . Asymmetric quadratic loss functions are produced under p = 2 and  $\alpha \neq 0.5$ .

The unknown loss function parameter  $\alpha$  is estimated by means of a linear instrumental variable (IV) approach. The computation of the linear IV estimator  $\hat{\alpha}$  is done iteratively. Using the same notation as in Elliott et al. [2005] we set the ini-

 $<sup>^{5}</sup>$ "Recursive" in the sense that for the calculation of the median in each period t only realizations up to t are used, not all observations from the eforecast evaluation sample. Otherwise the centering would contradict the real-time information flow and would not be feasible for actual forecasting.

<sup>&</sup>lt;sup>6</sup>When  $X_t$  is strictly exogenous without any feedback occurring from the forecast errors to future realizations of X the ranks of  $Z_t^k$  could also be used, and this would then indeed equal a Wilcoxon signed rank test on  $Z_t^k$ . This variant is not implemented, however, because the assumption appears very strong and hardly relevant in practice.

<sup>&</sup>lt;sup>7</sup>For historical reasons and backward compatibility the doEKTtest function up to FEP version 2.1 has operated on matrices. The preferred interface now is based on a bundle and series as described in this document. The doEKTtest\_series function has fulfilled that role since version 2.0. Starting with version 2.2 the doEKTtest function will follow the preferred interface (be an alias for doEKTtest\_series), and a new wrapper function doEKTtest\_matrix will provide the old access for those who need it.

tial weighting matrix S to be the identity matrix  $I_d$ , where d refers to the number of instruments used. Based on the initial S one can compute the initial  $\hat{\alpha}_1$  which in turn can be used to compute the precision matrix  $S^{-1} = (\hat{\alpha}_1)$ .FIXME formula means what??

These steps are repeated until some convergence criteria is met.

The user can use the framework to (i) test for symmetric loss, and (ii) for rationality. As  $\hat{\alpha}$  is asymptotically normal and its variance is identical to the one obtained by the standard GMM estimator, one can test the null of symmetry,  $H_0$ :  $\alpha = 0.5$ , against the alternative,  $H_0$ :  $\alpha \neq 0.5$ , by a t-test.

For a given  $p_0$  the user can test for rationality if the number of instruments d > 1. Testing for over-identification by means of a J-type test provides a joint test for rationality of the forecasts. The EKT approach allows to test for rationality (i) either for an unknown  $\alpha$  or (ii) by imposing the restriction of symmetry  $\alpha = 0.5$ .

See table 11 for the synopsis, and note that the instruments z should not contain an intercept, it will be added automatically.

### 4.5 Pesaran-Timmermann test on market timing – doPTtest()

While the Kuipers score just computes the difference between the hit rate, H, and the false alarm rate, F, it is not a proper statistical test. Pesaran and Timmermann (PT) have proposed a simple test on market timing using binary outcomes. The basic idea is to test whether predicted ups are independent of actual ups or not.

Let  $f = \{0,1\}$  be a forecast of the binary variable  $Y = \{0,1\}$ . Denote the corresponding time series of binary predictions as  $x_t$  and actual realizations of "ups" (or unity values) as  $y_t$ . How the forecaster obtains the forecasts  $x_t$  –e.g. through a model of a latent variable in the background– is irrelevant here.

The PT test statistic can be approximated by the t-ratio of the  $\beta_1$  coefficient of the following OLS regression

$$y_t = \beta_0 + \beta_1 x_t + u_t.$$

Under the null hypothesis that predictions and realizations are independently distributed, the restriction  $\beta_1 = 0$  holds. The test statistic follows asymptotically a standard normal distribution. A rejection of the null hypothesis indicates predictive failure. Serial correlation in the errors,  $u_t$ , are likely to occur but can be dealt with by using Bartlett weights to compute HAC standard errors.

A second –non-regression based– approach to compute the test instead is to rely on the correlation coefficient between forecasts and predictions,  $\rho$ . The test statistics is computed by  $\rho \times \sqrt{T}$  where T refers to the number of forecasts available. The test statistic also follows a standard normal distribution asymptotically and cannot be robustified.

See table 12 for a synopsis.

Function doEKTtest_series(bundle *b) from v2.2>  Description Elliott, Komunjer and Timmermann test for forecast rationality that allows for asymmetric loss none (void)  Function arguments Pointer to the model bundle. ### 4.6 Diebold-Lopez direction-of-change test – doDLtest()

Diebold & Lopez direction of change test which is in principle just Pearson's  $\chi$ -square test. H0: The direction-of-change forecast has no value meaning that the forecasts and realizations are independent. H1: The direction-of-change forecast has some value. (The side output of *DLinfo* is closely related to the Kuipers score, namely by adding unity to it.)

See table 13 for a synopsis.

# 5 Evaluation and comparison of multiple forecasts

#### 5.1 Diebold-Mariano test – doDMtest()

First, note that there also exists a dedicated contributed gretl function package called "DiebMar.gfn" by Giulio Palomba. It only partly overlaps with the features of the doDMtest() function, so it might be useful for you, too.

The Diebold-Mariano (DM) test of equivalent expected loss takes explicitly into account the underlying loss function as well as sampling variation in the average losses.

We define the h-step ahead forecast error and its associated loss function by  $e_{t+h|t}$  and  $L(e_{t+h|t})$ , respectively. The loss differential of two non-nested forecasts for observation t+h is given by  $d_{12,t+h}=L(e_{1,t+h|t})-L(e_{2,t+h|t})$ . Specifically, one

	Table 13: Diebold and Lopez test
Function Description	doDLtest(bundle *b) Diebold and Lopez test for predictive accuracy of a direction-of-change forecast
Return type	none (void)
Function arguments	Pointer to the model bundle. This bundle includes as members: series <i>yup</i> : binary-valued series of actuals that takes the value of unity for ups and otherwise zero series <i>fcup</i> : binary-valued forecast that takes the value of unity for ups otherwise zero scalar <i>verb</i> : 0 = no printout (default), 1 = print details
Output	The following new elements are stored into the model bundle: scalar <i>DLstat</i> : test statistic scalar <i>DLpval</i> : p-value scalar <i>DLinfo</i> : additional info value
Reference	Diebold and Lopez [1996]

can test the null hypothesis of equal predictive accuracy

$$H_0: E(d_{12,t+h}) = 0$$

against either an one-sided alternative or against a two-sided alternative. Under the null, the test statistics is  $DM = \bar{d}_{12,t+h}/\widehat{\sigma}_{\bar{d}_{12,t+h}} \to N(0,1)$  where  $\bar{d}_{12,t+h} = F^{-1}\sum_{j=1}^F d_{12,j,t+h}$  refers to the sample mean loss differential and  $\widehat{\sigma}_{\bar{d}_{12,t+h}}$  is a consistent estimate of its standard deviation based on F forecasts available.

However, due to serial correlation in the forecast errors, we compute alternatively the following regression-based version using OLS combined with HAC robust standard errors:

$$d_{12,t+h|t} = \beta + u_t$$

where  $u_t$  is an *i.i.d.* zero-mean error term. The null of equal forecast accuracy between the two point forecasts is defined as  $\beta = 0$ . The test statistics,  $t_{DM}$ , follows asymptotically a standard normal distribution.

Harvey, Leybourne and Newbold have suggested the following small-sample corrected degress-of-freedom adjusted t-statistics

$$t_{HLN} = [1 + F^{-1}(1 - 2 \times h) + F^{-2}h \times (h - 1)]^{0.5} \times t_{DM}$$

where F and h refer to the number of forecasts and the h-step forecast horizon. See table 14 for a synopsis.

Function Description Return type	doDMtest(bundle *b) Diebold and Mariano test for predictive accuracy, compute regression-based with HAC robust SEs none (void)
Function arguments	Pointer to the model bundle. This bundle includes as members: series <i>y</i> : realized values series <i>f</i> 1: forecast values of model 1 series <i>f</i> 2: forecast values of model 2 scalar <i>fhor</i> : forecast horizon (default 1) scalar <i>loss</i> : Loss function type: 1 = U-shape (default), 2 = V-shape scalar <i>verb</i> : 0 = print no details (default), 1 = print details
Output	The following new elements are stored into the model bundle: series <i>L</i> : loss differentials scalar <i>DMstat</i> : test statistics (not small-sample adjusted) scalar <i>DMpvaln</i> : p-value based on standard normal scalar <i>DMpvalt</i> : p-value based on t-distribution scalar <i>DMpvalssc</i> : p-value using small-sample correction

# 6 Menu-driven (GUI) usage

To install the FEP package using the GUI one follows the usual steps for contributed function packages: Open the function package list window for example via the menu File / Function packages / On server, then find the FEP entry and click the install button (or mouse right-click and choose Installation in the context pop-up menu).

For the precise meaning of the inputs to the respective functions please see the function documentation above, but ideally, using this package from gretl's menu interface should be mostly self-explanatory. From the menus you can only execute one test at a time.

Figure 1 shows the layout of the central window where choices and specifications are entered. In order to keep the number of argument fields in this window within reasonable bounds, some fields have different overloaded meanings depending on which test is chosen. For example, the penultimate entry field expects a gretl list, and this input is relevant for the HP, DL, EKT, and CG variants.<sup>8</sup>

The output from executing the function from the GUI is presented to the user in a new window, mostly simply with the printed test result. At the top of that output

<sup>&</sup>lt;sup>8</sup>This will be transferred internally to the various function arguments "z", "ref", or "CGX", respectively.

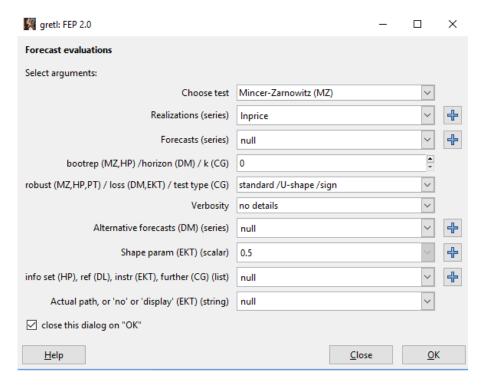

Figure 1: Screenshot of the FEP graphical interface (under Windows 10)

there is a toolbar including "save" and "bundle" icons. The save button allows you to save first the textual output, and secondly the whole produced bundle to the current gretl session. The bundle button in turn gives you direct access to the various produced bundle members which can also be saved.<sup>9</sup>

Note that only the actual test functions are choosable from the GUI, not the helper functions from section 3.

# 7 Illustrative example

In the following an applied example using survey-based forecasts for annual growth of euro area (EA) real GDP is presented. Forecasts are averages based on surveys among professional forecasters,  $fc_t$ , conducted by the Economist magazine and obtained through the Macrobond database. The realizations,  $y_t$ , are from the AMECO database provided by the European Commission. Figure 2 depicts the forecast errors,  $e_t = y_t - fc_t$ . In the following the main (but not all) functions of the FEP package are applied.

<sup>&</sup>lt;sup>9</sup>The concrete images of those icons will depend on your OS and/or your desktop theme, but they are the first two buttons from the left.

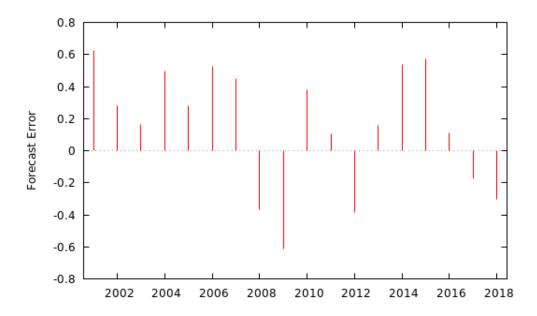

Figure 2: Forecast error for euro area growth of real GDP

#### 7.1 Tests of unbiasedness

We run the parametric Mincer-Zarnowitz test on forecast unbiasedness using bootstrap p-values (999 iterations, *iid*) and HAC standard errors, see section 4.1. First an empty bundle is defined, then the series and parameters are added:

```
bundle b = null
series b.y = y  # realizations
series b.fc = fc # forecasts
b.nboot = 999
b.robust = 1 # 1= HAC robust VCV
b.verb = 1  # 1=print details
applyFCtests(&b, "MZ") # call the top-level function
*** OUTPUT ***
Method: Approach using HAC robust VCV.
Bootstrap p-value using 999 iterations.
HO: forecasts are unbiased
Test stat.: 5.6758
p-value.: 0.3874
```

As can be seen, the null hypothesis cannot be rejected at standard levels which indicates that the forecast errors are unbiased.

A non-parametric alternative test approach for forecast unbiasedness was proposed by Campbell and Ghysels, as discussed in section 4.3. Assuming that the previous code has been executed and thus b, b.y, b.fc and b.verb are already defined, the CG test can be performed as follows:

```
applyFCtests(&b, "CG")
printf "P-value Wilcoxon-type rank sign test = %.3f\n", b.CGWILCpval
printf "P-value sign test = %.3f\n", b.CGSIGNpval
*** OUTPUT ***
P-value Wilcoxon-type rank sign test = 0.122
P-value sign test = 0.096
```

These nonparametric tests do not provide strong evidence against unbiasedness, either. However, if a researcher assumed an underlying asymmetric distribution the only adequate test would be the nonparametric sign test, which might be considered borderline significant here.<sup>10</sup>

### 7.2 Tests of efficiency

The Holden-Peel test is a parametric test of efficiency, see section 4.2. We simply use lagged forecasts,  $fc_{t-1}$ , as the conditional variable. The HP test with bootstrap HAC standard errors is easily executed by:

```
list b.z = fc(-1) # use lagged forecast as conditional variable
applyFCtests(&b, "HP")
*** OUTPUT ***
Method: Approach using HAC robust VCV.
Bootstrap p-value using 999 iterations.
HO: forecasts are efficient
Test stat.: 8.1013
p-value.: 0.2853
```

Hence, this parametric test result does not indicate any issue with forecast efficiency conditional on  $fc_{t-1}$ .

A non-parametric version is also provided by the CG test approach which can be used as follows: FIXME... k/CGX siehe email...

```
b.k = 1
series b.CGX = fc(-1)
smpl fc(-1) --no-missing # avoid NAs in the sample
applyFCtests(&b, "CG")
printf "P-value Wilcoxon-type rank sign test = %.3f\n", b.CGWILCpval
printf "P-value sign test = %.3f\n", b.CGSIGNpval
*** OUTPUT ***
```

<sup>&</sup>lt;sup>10</sup>The empirical skewness in this sample is -0.6. A skewed distribution would obviously imply non-Gaussianity; the Shapiro-Wilk test of the null of a normal distribution yields a p-value of 0.096, the Doornik-Hansen test in turn produces 0.152, thus somewhat borderline again.

```
P-value Wilcoxon-type rank sign test = 0.008
P-value sign test = 0.001
```

Thus, the non-parametric test raises doubts that the forecasts have made efficient use of available information, as the null can be safely rejected at the 1% level.

### 7.3 Tests of (a)symmetric loss and forecast rationality

The framework proposed by Elliott et al. [2005] extends parts of the previous analysis to the case of asymmetric loss functions, cf. section 4.4. We will use lagged forecast errors as an additional instrument apart from an intercept for illustration, and assume a quad-quad loss function. (Strictly speaking, the explicit specification of b.loss is redundant, since the quadratic U-shape is the default, see Table 2.)

```
b.loss = 1 # Loss function (1=quad-quad, 2=lin-lin)
series fcerr = y - fc
series fcerr1 = fcerr(-1) # additional instrument
list b.z = fcerr # instrumental variable FIXME: fcerr1 ??
smpl fcerr fcerr1 --no-missing
b.a0 = 0.5 # Initial value of shape parameter aT
string b.lossdraw = "display"
applyFCtests(&b, "EKT")
*** OUTPUT ***
* Test for Symmetry: H0: aT=0.5 vs. H1: aT!=0.5
Estim. alpha = 0.236, Test stat. = -2.41, P-value = 0.0158
* Rationality Test
Estim. alpha = 0.236, J-statistics = 1.46, P-value = 0.227
* Rationality Test
Alpha fixed to 0.5, J-statistics = 7.28, P-value = 0.0262
```

The null of symmetric loss can be rejected at the 5% level, and after imposing symmetry anyway one would indeed reject the null of forecast rationality at the 5% level. However, under the estimated asymmetric loss function one cannot reject the null of forecast rationality. Here the suggested conclusion is that the forecasts may be regarded as "rational", but only if one departs from the assumption of a symmetric forecast error loss function.

The estimated  $\hat{\alpha}$  is 0.236 which indicates greater aversion to negative forecast errors. This is perhaps not surprising considering the sequence of positive forecast errors in the first part of the sample. Apart from the reported test results, a plot of the estimated loss function is returned (see Figure 3). The upper and lower lines represent a confidence band due to the estimation uncertainty of the asymmetry parameter  $\hat{\alpha}$ .

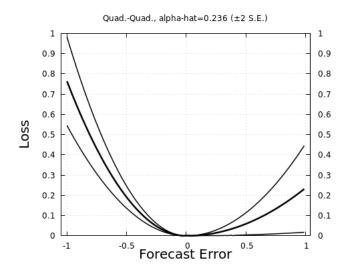

Figure 3: Estimated loss function using the EKT approach

### 7.4 Forecast comparison

The Diebold-Mariano approach tests for equal predictive accuracy of two competing forecasts (section 5.1). We compare the current forecast for simplicity with the pre-year (naive) forecast assuming linear loss. The test is called by:

```
b.f1 = fc  # FC 1 series
b.f2 = y(-1) # FC 2 series: naive pre-year realization
b.loss = 2 # 1="U-shape", 2="V-shape"
applyFCtests(&b, "DM")
*** OUTPUT ***
Loss: V-shape linear.
Forecast horizon: 1
H0: forecasts are equally accurate
Test stat.: -2.5611
p-value (stand. normal): 0.0104
p-value (t-distributed): 0.0209
p-value (small-sample): 0.0178
```

The null hypothesis can be rejected at the 5% significance level for all three versions computed. The negative test statistic (-2.56) indicates that the "real" survey-based forecast is more accurate compared to the naive one.

### 7.5 Directional forecast

Apart from point forecasts, directional forecasts may be of interest. The *Kuipers* score (KS) is a widely applied simple statistic to summarize directional forecasts, see section 3.3.1. The following lines first compute the dummy variables yup and

f cup which take the value of one if the period-change in realized (or forecast) values is positive (otherwise zero), and then execute the KS computation.

```
series b.yup = (diff(y) > 0)
series b.fcup = (diff(fc) > 0)
applyFCtests(&b, "KS") # could also use doKS(&b)
*** OUTPUT ***
Hit Rate = 1.000
False Alarm Rate = 0.100
Kuipers Score = 0.900
```

Accordingly, the forecasts have a perfect hit rate of 1 meaning that all "ups" are correctly predicted. The false alarm rate is only 10% such that the KS statistic is 0.9 which indicates a good directional forecast performance.

Finally, the *Diebold-Lopez* test (section 4.6) tests whether a directional forecast is significantly different from a coin flip. The relevant script is provided in the listing below, where we re-use the previously defined series b.yup and b.fcup. The positive test statistic of 1.88 indicates that the actual forecast outperforms a pure coin flip which is statistically confirmed by the p-value.

```
applyFCtests(&b, "DL")
*** OUTPUT ***
H0: y(t) and fc(t) are independent
Info-value: 1.8750
Test stat.: 13.3875
p-value.: 0.0003
```

In this context the Pesaran-Timmermann test described in section 4.5 may be seen as an alternative test for directional forecasts.
